

Deep Generative Models

Chapter 3: Generation by Explicit Distribution Learning

Conventional Data Generation

In conventional approaches, we *learn the data distribution* and *sample it*!

Data Samples: Arrays of Unit Components

Let's assume $x = \text{DataType} \{x_1, \dots, x_d\}$ for some *data-type*

- This *data-type* could be any form of *array*
 - ↳ Tensor of pixels or *pixel-patches*
 - ↳ A sequence of scalars, vectors or tensors
- x_j for $j = 1, \dots, d$ are *unit components*
 - ↳ They could be scalars or fixed-size tensors
 - ↳ We assume that the space of x_j is *small and manageable*

We refer to d as *data dimension*

- ↳ This is in practice *very large*

Generation by Sampling

Assume we **trained** the model $P_{\mathbf{w}}(x)$: we intend to **generate** a new sample

- + Well, we simply **sample the trained $P_{\mathbf{w}}(x)$** ! Right?!
- Sure! But, let's see how **simple** is **sampling** on our computer!

Say every x_i is a **discrete variable** with C possible outcomes, i.e.,

$$x_j \in \mathbb{A} = \{a_1, \dots, a_C\}$$

The question that we intend to answer is

+ How **complicated** is it to **sample** from $P_{\mathbf{w}}(x)$?

Recap: Sampling a Multinomial Distribution

Example: Say $u \sim \text{Unif}(0, 1)$ is **uniformly** distributed between 0 and 1. We pass u through the **following thresholding function** to build x as

$$x = 0 \text{ if } 0 \leq u < p \text{ and } p \leq u \leq 1$$

The **new variable** x is distributed as $P(x = 1) = 1 - P(x = 0) = p$

↳ We can sample a binary variable by thresholding a uniform sample u !

This is how the computer samples a **multinomial** distribution: to sample from the **multinomial** distribution $\mathbf{p} = [p_1, \dots, p_C]$ with C outcomes

↳ **Break** the interval $[0, 1]$ with **levels proportional to** $p_1, \dots, p_C$

↳ Sample a **uniform variable** $u \sim \text{Unif}(0, 1)$

↳ **Threshold** u with the levels

Recap: Sampling a Multinomial Distribution

Sample($\mathbf{p} = [p_1, \dots, p_C]$)

1: *Sample a standard uniform u*

$u \sim \text{Unif}(0, 1)$

2: **for** $c = 1 : C$ **do**

3: Check if u is between $\sum_{j=1}^{c-1} p_j$ and $\sum_{j=1}^c p_j$

4: **end for**

5: **return** outcome of the valid interval

Moral of Story

To sample a **multinomial** distribution with C possible outcomes, we need to do $\mathcal{O}(C)$ computational operations

Sampling Complexity

Back to our problem: we have

$$x = \text{DataType} \{x_1, \dots, x_d\}$$

with *each* x_j having C possible outcomes

- + How *complicated* is it to sample from $P_{\mathbf{w}}(x)$?
- Let's do a simple calculation

$$\# \text{ of outcomes for } x = C^d \rightsquigarrow \text{complexity} = \mathcal{O}(C^d)$$

Conclusion

Even if we have *trained* $P_{\mathbf{w}}(x)$ perfectly, it's *exponentially hard* to sample from the *trained* model!

Sampling Complexity

- + Is it the same story if x_j is *continuous*?
- Yes!

To *sample* a target density function on computer

- 1 Sample a *Gaussian distribution*
- 2 Pass it through a *transform* computed using C density values

Similar to *discrete* case

of density values required for $x = C^d \rightsquigarrow$ *complexity* = $\mathcal{O}(C^d)$

- + So, it seems *impossible* then!
- Keep this in mind! We will get rid of it by *various approaches*

Training: *Primary Assumptions*

To train the model, we use **maximum likelihood estimation (MLE)**

Likelihood (*formal*)

Likelihood of **model** $P_{\mathbf{w}}$ computed on $\mathbb{D} = \{x^i \text{ for } i = 1, \dots, n\}$ is defined as

$$\mathcal{L}(\mathbf{w}) = P_{\mathbf{w}}(\mathbb{D})$$

Note that we need **joint distribution**; however, we assume **i.i.d. samples**

Basic Assumption: *i.i.d. Dataset*

We assume that x^j are **independently** sampled from data distribution; thus,

$$\mathcal{L}(\mathbf{w}) = \prod_j P_{\mathbf{w}}(x^j)$$

Training via MLE

To train the model, we **maximize** the **log-likelihood** function

$$\mathbf{w}^{\star} = \underset{\mathbf{w}}{\operatorname{argmax}} \log \mathcal{L}(\mathbf{w}) = \underset{\mathbf{w}}{\operatorname{argmax}} \frac{1}{n} \sum_j \log P_{\mathbf{w}}(x^j)$$

- + But, why is **MLE** a **good** approach?
- There are two ways to see it: **intuitive** and **through divergence**

Intuitive Justification of MLE

We know that the data-space is **huge** as compared to the **number of samples**

- the collected samples are the **most-likely ones**
- the probability of **them** happening together should be **very high**

To illustrate the second view: we *need to recap the notion of* **divergence**

Recap: Kullback-Leibler Divergence

As seen in Assignment 1: two *distributions* can be compared via *divergence*

- ↳ If they are *the same* $\rightsquigarrow$ the *divergence* is *zero*
- ↳ The more *different* they are $\rightsquigarrow$ the *larger* the *divergence* will be

Kullback-Leibler Divergence

KL divergence between two distributions $P(x)$ and $Q(x)$ is defined as

$$D_{\text{KL}}(P\|Q) = \sum_x P(x) \log \frac{P(x)}{Q(x)} = \mathbb{E}_{x \sim P} \left\{ \log \frac{P(x)}{Q(x)} \right\}$$

Properties of KL Divergence

- ① Each distribution is in **divergence zero** from **itself**

$$D_{\text{KL}}(P\|P) = \mathbb{E}_{x \sim P} \left\{ \log \frac{P(x)}{P(x)} \right\} = \mathbb{E}_{x \sim P} \{ \log 1 \} = 0$$

- ② **KL divergence** is always **non-negative** $\rightsquigarrow$ **Gibbs' Inequality**

$$D_{\text{KL}}(P\|Q) = \mathbb{E}_{x \sim P} \left\{ \log \frac{P(x)}{Q(x)} \right\} \geq -\log \mathbb{E}_{x \sim P} \left\{ \frac{Q(x)}{P(x)} \right\} = 0$$

↑
Jensen Inequality

Attention: KL divergence is not symmetric

$$D_{\text{KL}}(P\|Q) = \mathbb{E}_{x \sim P} \left\{ \log \frac{P(x)}{Q(x)} \right\} \neq \mathbb{E}_{x \sim Q} \left\{ \log \frac{Q(x)}{P(x)} \right\} = D_{\text{KL}}(Q\|P)$$

Estimating KL Divergence

Note that **KL divergence** is given as an **expectation**: we can use the **law of large numbers** to **estimate** it from a large number of **samples**

Law of Large Numbers (LLN) (informal)

Assume $\{x^j \text{ for } j = 1, \dots, n\}$ are i.i.d. samples from $P(x)$; then,

$$\frac{1}{n} \sum_j F(x^j) \rightarrow \mathbb{E}_{x \sim P} \{F(x)\}$$

for a function $F(\cdot)$ as $n \rightarrow \infty$

So, we can estimate the KL divergence from **dataset $\mathbb{D}$** as

$$\hat{D}_{\text{KL}}(P \| Q) = \frac{1}{n} \sum_j \log \frac{P(x^j)}{Q(x^j)}$$

Another View: MLE as Divergence Minimization

- + But, what kind of *estimate* is it?! We still *need* P !
- Well! We *only* need to *evaluate its value at sample points*!

- + Ready for the *alternative* viewpoint?!
- Yes! An *alternative viewpoint* on *MLE* is that

MLE *minimizes KL divergence* between *model* and *data distribution*

Another View: MLE as Divergence Minimization

Genie-aided Power

A **genie** can compute **data distribution** at an **arbitrary point** for us, i.e., if a **point** x^j from the data-space is given $\rightsquigarrow$ the **genie** can give us $P(x^j)$

With the help of the **genie**, we can use dataset $\mathbb{D}$ to **estimate** the **KL divergence** between **data distribution** $P(x)$ and **generative model** $P_{\mathbf{w}}(x)$

$$\Delta(\mathbf{w}) = \hat{D}_{\text{KL}}(P \| P_{\mathbf{w}}) = \frac{1}{n} \sum_j \log \frac{P(x^j)}{P_{\mathbf{w}}(x^j)}$$

Looking at this estimate, we can say

- This **estimate** depends on the **model parameter** $\mathbf{w}$
- The **right way to train** the model $P_{\mathbf{w}}(\cdot)$ is to **minimize** this **estimate**

$\hookrightarrow$ As the **divergence** goes to **zero** $\rightsquigarrow$ $P_{\mathbf{w}} \rightarrow P$

Another View: MLE as Divergence Minimization

So, the model with **minimal** KL **divergence** from **data distribution** is learned as

$$\begin{aligned}
 \mathbf{w}^* &= \underset{\mathbf{w}}{\operatorname{argmin}} \Delta(\mathbf{w}) = \underset{\mathbf{w}}{\operatorname{argmin}} \hat{D}_{\text{KL}}(P \| P_{\mathbf{w}}) \\
 &= \underset{\mathbf{w}}{\operatorname{argmin}} \frac{1}{n} \sum_j \log \frac{P(x^j)}{P_{\mathbf{w}}(x^j)} \\
 &= \underset{\mathbf{w}}{\operatorname{argmin}} \left[\frac{1}{n} \sum_j \log P(x^j) - \frac{1}{n} \sum_j \log P_{\mathbf{w}}(x^j) \right] \\
 &= \underset{\mathbf{w}}{\operatorname{argmax}} \frac{1}{n} \sum_j \log P_{\mathbf{w}}(x^j)
 \end{aligned}$$

Bingo! This is indeed **MLE**!

↳ and we do **not** really need the **genie** 😊

MLE: Final Notes

MLE $\equiv$ KL Divergence Minimization

Maximum likelihood learning make sense, since it **minimizes** the KL **divergence** between the **model** and **data distribution**

- ↳ We can only **estimate** KL **divergence** using the **dataset**
- ↳ Clearly, there is some **estimation error** $\rightarrow$ **that's what it is!**

Attention

Note that even in perfect training log-likelihood does **not** get to **zero necessarily!**

$$\hat{D}_{\text{KL}}(P \| P_{\mathbf{w}^*}) = 0 \rightsquigarrow \frac{1}{n} \sum_j \log P_{\mathbf{w}^*}(x^j) = \frac{1}{n} \sum_j \log P(x^j) = -\hat{H}(P)$$

where $\hat{H}(P)$ is the **estimate** of **data entropy**

Summary of Conventional Approaches

minimizes $\hat{D}_{\text{KL}}(P|P_{\mathbf{w}})$

complexity = $\mathcal{O}(C^d)$
